1. INTRODUCTION

The Survey of Income and Program Participation (SIPP) collects data on assets and liabilities because of their importance in determining program eligibility and in assessing the economic situation of families. Questions concerning the ownership and amounts of assets and liabilities were included in the supplement to the fourth interview of the 1984 panel (collected in September through December 1984). These were updated one year later in wave 7. The current SIPP design collects wealth data on a yearly basis.

Viewed longitudinally, collecting asset and liability data two times per panel provides the potential to measure consumer savings, i.e. the change in asset equity. Response errors and variance about the point-in-time estimates, however, make it difficult to measure consumer savings. Measurement errors directly affect microlevel measures of savings. While over or underestimates of wealth may cancel out at the aggregate level, such measurement errors do not necessarily cancel out for savings estimates at the individual level. For example, it is possible to have an overestimate of an asset value in the first interview followed by an underestimate of the value at the following interview for the same individual, which result in an underestimate of the change in the asset value or savings. At the aggregate level, however, such underestimates of savings may cancel out overestimates for other individuals.

In an effort to measure microlevel changes in wealth, a test was implemented to provide (or feedback) information collected in previous interviews to respondents during the current interview. Specifically, information on asset and liability values collected in wave 4 was provided to respondents interviewed in wave-7. The rationale for the feedback system was that respondents would provide more accurate estimates of change if they were first reminded of the amount they reported the previous year. If respondents

knew the amount of the change in asset value and were reminded of their beginning balance, then their reporting of their current balance would be consistent with the amount of change over the period.

In this paper, we evaluate the results of the feedback experiment. To evaluate the results of the feedback project, it would be useful to compare the results to microlevel information on individual savings from administrative records. However, there are no microlevel administrative record sources available to benchmark household savings estimates from SIPP. One option would be to obtain releases from respondents and obtain information on each asset and liability directly from financial institutions, such as banks, credit unions, lenders, etc. That option, however, would be very expensive and is beyond the scope of the feedback experiment and this paper. As an alternative, a split sample approach was conducted in order to test the feedback approach. One half of the eligible households were interviewed using a feedback form (feedback group), while the other half were independently interviewed, that is, without the previous information (control group). With this split sample design, it is possible to compare the methods of collections and judge the "reasonableness" of the data collected in order to draw inferences about the quality of the feedback based data. Savings are expected to be related to employment patterns, age of the householder, income level, and household composition. Information in SIPP for the person and household can be used to assess the data. For example, income is positively correlated with savings, while periods of unemployment are expected to be negatively correlated with savings. In addition, changes in household composition due to a divorce/separation or a death in the family will affect the change in

household net worth. Comparing the savings patterns from the feedback group and the control group using other economic information available in the survey can give an indication of the impact of the feedback procedure. In this paper, we address two questions. First, what effect does the feedback approach have on net worth and savings estimates? And second, do the results warrant the further use of the feedback approach on future SIPP wealth modules?

A description of the experiment is presented in the next section and an analysis of the results is discussed in the following two sections: one concentrating on aggregate net worth estimates, and the other concentrating on microlevel estimates of savings. In the final section, we draw some conclusions based on the data presented in this study.

II. DESCRIPTION OF THE FEEDBACK SYSTEM

SIPP is a panel survey in which households are interviewed every four months for a period of two and one-half years. At each interview, information on income, program participation, and other characteristics is obtained for each month of the reference period for each person in the household. In addition, at each interview the questionnaire is expanded with supplemental questions on selected topics, called topical modules. Detailed questions concerning the amounts of personal and household assets and liabilities were included at one year intervals in the fourth and seventh interviews of the 1984 panel which were conducted in September through December 1984 and 1985, respectively.¹ These modules provide sufficient information to estimate

¹The reference date for the asset and liability questions was the last day of the four month reference period that preceded the interview. As a result, the data presented in this study are an average of balances held and owed at the end of the months August, September, October, and November 1984 and 1985.

household net worth. Net worth is defined as the value of assets minus liabilities owed. The assets covered in the wealth modules included interest-earning assets², stocks and mutual fund shares, real estate (own home, rental property, vacation homes and other holdings), own business or profession, mortgages held by sellers, motor vehicles, and other financial investments. The liabilities covered were any secured debts (e.g., mortgages, automobile loans, margin accounts, and debts on business), bank loans, credit card balances, doctor bills, and other unsecured loans. The survey did not cover equities in pension plans, cash surrender value of life insurance policies, or the value of jewelry or home furnishings.

The SIPP uses a feedback procedure to collect asset ownership information in each wave. In the initial interview, a set of detailed questions designed to identify ownership of income earning assets are asked for each person in the household. An asset roster is created and recorded on the control card. In subsequent interviews, the respondent's asset roster for the previous wave is checked for accuracy and is then updated for any asset liquidations or acquisitions. With this procedure, relatively accurate asset ownership information is obtained before respondents are asked about asset values and liability amounts in the fourth and seventh waves.

As a longitudinal survey which collects wealth data two times per panel, SIPP provides the opportunity to estimate the change in net worth or savings. Few household surveys have attempted to measure savings. The 1962-1963

²Interest-earning assets are regular savings accounts, money market deposit accounts, certificate of deposits, checking accounts, money market funds, corporate or municipal bonds, U.S. Government securities, IRA and KEOGH accounts, and other interest assets.

Survey of Financial Characteristics used estimates of wealth holdings at one year intervals to analyze patterns and amounts of savings by the characteristics of persons and households [Projector and Weiss, 1966].³ The 1977 Consumer Credit Survey asked whether savings increased or decreased but did not obtain information on amounts [Durkin and Elliehausen, 1978]. Finally, the wealth data collected in the 1983 Survey of Consumer Finances was updated in 1986.

The difficulty of collecting accurate wealth data in household surveys has long been recognized and documented [Projector and Weiss 1966; Smith, 1983; and Lamas and McNeil, 1984]. Response and sampling errors in each cross sectional estimate create further problems in measuring the change in asset values. The feedback system was designed to provide selected asset and liability information as a reference during the wave 7 interview. The information was computer generated for key items from the wave 4 file. An example of the feedback form is presented in Appendix A. Two features about the design of the form should be noted. First, the information on the form closely parallels the information being collected in wave 7. Second, the form is at the person level. A form was generated for each person in the household for whom an interview was obtained for wave 4. Information on balances held in the sample person's own name is shown in the second column. For husband and wife families, information on jointly held assets and liabilities is shown in the first column of both spouses' feedback forms. This simplified the interview process since the sequential order of interview was not important: the jointly held assets were covered during the interview for the first spouse.

³The Survey of Financial Characteristics used a similar feedback procedure in the 1964 interview. The amounts reported in the 1963 interview were provided to the respondent on the questionnaire form.

At the beginning of the asset and liability portion of the interview, the interviewer read to the respondent an introductory statement printed at the top of the form (see Appendix A). The statement explained that the form contained information collected one year ago and should be used by the respondent as a reference when similar items were asked during the interview. In the course of the interview, when an interviewer asked an asset or liability item, the respondent was referred to a line item on the feedback form where an amount from Wave 4 was shown. The respondent used the information in formulating an answer. If the respondent indicated that the amount on the feedback form was incorrect, space was provided on the feedback form for the correct amount to be entered. Since explicit and systematic verification of feedback amounts was more complicated than desirable for this research effort, only corrections voluntarily provided by the respondent were collected.

The feedback process raised some concern about confidentiality of the information. Proxies are often used in interviews. Therefore, the situation was likely to arise where wave 4 information for an individual is disclosed to a proxy respondent. To minimize concern over release of confidential information, feedback forms were used only when a self-respondent or the same proxy-respondent as in wave 4 was interviewed.

There was one operational difficulty with use of the feedback form which should be noted. As stated previously, the feedback form was a computer generated printout of the financial information and the respondents identification

code.⁴ The respondent's name was not used to protect the confidentiality of the data. Interviewers and the regional office staff reported that many respondents expressed a negative reaction to having their financial information on a computer form. During the course of the panel, interviewers often stress to respondents that their data is confidential and protected under the law (Title 13 of United States Code), and that the Census Bureau only releases statistical data which do not allow a third party to identify the respondent. While the Census Bureau has the responsibility to protect the confidentiality of the information, many respondents were uncomfortable with the fact that their information was maintained in computers and was then able to be reported at the individual level. While there may have been some negative effects with the use of a computer form, there was no evidence that it affected response rates. It would be possible to devise a feedback system which avoids the use of computer generated forms, for example, by having interviewers to transcribe amounts to the questionnaire.

III. RESULTS

A. Cross-sectional Estimates of Mean and Median Net Worth

Estimates of median and mean household net worth for the control group and for households eligible for the feedback form are shown in tables 1 and 2

⁴The respondent identification code is based on the regional office code number and various sampling information, such as the primary sampling unit (PSU) number, segment and serial numbers, address and entry address numbers, and person number.

respectively. The standard errors of these estimates are shown in Appendix B, tables A and B. Estimates for both wave 4 and wave 7 have been weighted to represent all U.S. households when the control and feedback groups are added together. The wave 7 figures, were adjusted for changes in the Consumer Price Index, and are shown in 1984 constant dollars. For the control group, the year-apart estimates show a \$1,160 decline in median net worth (from \$32,048 to \$30,890) and a \$741 increase in mean net worth (from \$77,223 to \$77,964). These changes, however, were not statistically significant. For the feedback group, there was a \$590 decline in median net worth (from \$32,940 to \$32,360) and a \$860 decline in the mean net worth (from \$80,030 to \$79,160). Again, these changes were not statistically significant.

The data show similar trends in net worth across population subgroups for the control and feedback groups. For example, the ratio of median net worth in wave 4 and wave 7 of older (65 and over) to young householders (less than 35) was approximately 11 to 1 for both the control and feedback group. Similarly, the ratio of median net worth of White to Black households was approximately 11 to 1, and the ratio for the highest to lowest income quintile was approximately 20 to 1. Estimates of equity in specific asset types were similar for the control and feedback groups. For example, median equity in own home was \$40,500 for home owners in wave 4 and \$39,000 in wave 7 for both the control group and feedback group. For interest-earning deposits at financial institutions, (savings accounts, money market deposit accounts, certificates of deposit and interest-earning checking accounts), the estimates were approximately \$3,000 in wave 4 and wave 7 for the control and feedback groups..

Similar trends for subgroups of the population were also found for the feedback and control groups when using mean net worth estimates. For example, the ratio of mean net worth in wave 4 and wave 7 for the older to younger householders was approximately 5 to 1, the ratio of mean net worth of White to Black households was about 4 to 1, and for the highest to lowest income quintile was approximately 6 to 1. Mean equity in own home was approximately \$50,000 in wave 4 and \$51,500 in wave 7 and mean value of interest-earning assets were approximately \$15,000.

When we examined the year-to-year changes in net worth within subgroups, however, there were very few changes which were statistically significant for either the control or feedback groups. (Statistically significant differences in tables 1 and 2 are denoted by an asterisk.) In general, the changes were similar for control and feedback groups, that is, for the same subgroups and in the same direction. For example, changes in median net worth by age of the householder declined by about \$5,000 (or 10 percent of median net worth) for householders 45 to 54 years old in both the control group and feedback group. Estimates for the control group declined in the less than 35 years old and 55 to 64 years old groups and the changes were in the same direction, but not statistically significant for the feedback group. The estimates of change in the value of holdings of specific asset types were also similar between the two groups. For example, median value of equity in own home declined by \$1,700 in the control group and \$1,540 in the feedback group, while median value of IRA or KEOGH accounts increased by \$1,130 and \$1,450 for the control and feedback group, respectively.

The interpretation of changes in these two point-in-time estimates is difficult, however, because households can change in composition over time and because the data were processed independently. Households change over time as members move in or out for various reasons, such as due to separation/divorces or employment changes. In addition to changes in household composition, the analysis must consider the problems of noninterviewers and item nonresponses. Approximately 11 percent of the households eligible for the first wave interview were noninterviews in wave 4, and the rate was 17 percent in wave 7. These noninterview rates compare favorably to the rates in other wealth surveys. Item nonresponses occur when respondents do not answer a question, either due to a refusal or a lack of knowledge. For these items, the missing information was imputed by using reported information from a donor with similar characteristics to replace the missing information. The wave 4 and wave 7 data were processed independently: information from one wave was not used to impute the other.

Table 3 shows the proportion of the total value of assets that was imputed. The results show that a substantial proportion of the value of assets was imputed. Imputations accounted for approximately 40 percent of the value of stock and mutual fund shares, 30 percent of rental property, and about 20 percent of own homes, other real estate and IRA's. These rates were generally similar for both wave 4 and wave 7.

To analyze savings estimates holding household composition constant and using only reported data in both interviews, the information in wave 4 and 7

for the households must be matched. The next section examines such microlevel changes in net worth for various types of households.

B. Microlevel Changes in Net Worth

In addition to cross-sectional estimates of net worth, it is possible to measure changes in net worth at the individual household level. We started by taking households in wave 7 and matching them back to wave 4. The procedure took the reference person in wave 7 and matched them back to the household he/she was a member of in wave 4. We classified the matched households as having the same composition if each adult in wave 7 was present in the wave 4 household, and each adult in wave 4 was present in the wave 7 household.⁵ It should be noted that because of a sample cut between the two waves, the results from the matched file are not strictly comparable to the cross-sectional derived estimates from wave 4 and wave 7. Some households were not present in wave 7 because of a sample reduction that occurred between the two waves.

Table 4 shows the distribution of the change in net worth from wave 4 to wave 7 by type of household. Since the imputation procedures in wave 4 and wave 7 were independent, results are shown by whether any of the net worth data in wave 4 or wave 7 was imputed or it was all reported in both interviews. When comparing the results of some imputation versus no imputation, it is clear that microlevel estimates of change produced by two independent consistency edit and imputation procedures cannot be expected to be reasonable. Matched households with some imputations showed much greater changes in net

⁵For the analysis of saving, we defined adults as any person 18 years of age or older. The rationale for this age cutoff was that the movement of persons over 18 years of age have greater impact on household net worth than persons under 18.

worth. Sixty-two percent had increases or decreases of \$10,000 or more and only 8.1 percent had a small change in net worth (of \$1,000 or less). In comparison, 34.5 percent of matched households without imputations had increases or decreases of \$10,000 or more while 22.8 percent had a small change less than \$1,000 in net worth. This suggests that a longitudinal consistency edit and imputation system is necessary to produce estimates of change in net worth. The majority of households had some items imputed. Sixty percent of households had one or more net worth items imputed in wave 4 or wave 7.

Table 4 shows estimates for households with no change in composition and for a certain set of households that did have a change in composition. Households without a change in composition had, on average, an increase in net worth. Married-couple households had an average increase of \$5,329, for example, although 34 percent had a decrease of \$1,000 or more and 15 percent had a decrease of \$10,000 or more. The universes for two groups of households that did have a change, wave 7 widows who were married-spouse present in wave 4, and wave 7 divorced or separated women who were married-spouse present in wave 4, are quite small. The data show an average net worth increase of \$13,000 for the widows and an average decrease of \$11,000 for the divorced and separated. It is difficult to determine the extent to which these estimates reflect real changes and the extent to which they represent measurement problems. We can start by considering that only 2 percent of households have annual incomes of \$100,000 or more. For 98 percent of households, then, a change in net worth of \$10,000 is a substantial change. If asset prices were stable, a \$10,000 increase in net worth would mean that more than 10 percent of current income had been saved. Of course,

asset prices were not stable during our reference period. The value of the average share of stock listed on the New York Stock Exchange increased by 12 percent from late 1984 to late 1985. Our data from SIPP, however, show that only about 20 percent of households owned stock and the average value of stock portfolios was about \$27,000 in late 1984. Given these considerations, it seems likely that changes of \$10,000 or more are substantial changes for most households.

There is some evidence that the feedback procedure reduces the estimates of change. Table 5 presents data for those matched households with no imputation who were in the feedback sample. The mean difference in net worth for this group was \$1,947 versus \$3,387 for matched, nonimputed households who were not in the feedback sample (Table 6). The proportion of feedback sample households with changes of \$10,000 or more was 33 percent for the feedback sample and 36 percent for the nonfeedback sample.

The data in tables 5 and 6 show a reasonable relationship between income level and change in net worth. One would expect that large changes would be more common for high income household than for low income households and the data support this expectation. For the feedback group, approximately 37 percent of households in the highest income quintile had an increase of \$10,000 or more, 24 percent had a decrease of \$10,000 or more, and 6 percent had a change of less than \$1,000. In comparison, 9 percent of households in the lowest quintile had an increase of \$10,000 or more, 7 percent had a decrease of \$10,000 or more, and 50 percent had a change smaller than \$1,000.

In order to estimate the marginal effect of various characteristics on savings estimates, we used the SIPP data to fit a simple model of savings in which the change in net worth is a function of the level of total net worth and income at the beginning of the period, the change in income during the period, and certain characteristics of the householder including age, marital status, and race and ethnicity. The set of observations was limited to those households without a change in composition who had no imputed net worth items. Separate regressions were estimated for the control group and feedback group.

The results of regressing the change in net worth on the independent variables are summarized in Table 7. The regressions were significant and the R^2 for the feedback group (.12) was about twice that of the control group (0.6). In general, the results for the independent variables were similar for both groups. The income variables had a significant positive effect on savings, wave 4 net worth had a negative and significant coefficient, the age groups "less than 35" and "45 to 54" had a significant negative effect, and the other variables were not significant. These regressions are consistent with the results obtained by Projector when she regressed 1963 savings on 1963 disposable income and December 1962 net worth. In that study the coefficient of income was positive, the coefficient of net worth was negative, and the R^2 was .04 [Projector and Weiss, 1968].

IV. CONCLUSION

In this paper we have examined the year-to-year changes in household net worth and whether the feedback experiment provided more consistent measures of change. No definite answer about the impact of the feedback approach can be provided because benchmark data for savings are not available. However, we have provided some evidence on the effect of the feedback approach by examining the estimates from the feedback group and control group in order to draw some inferences about data quality. In general, we found that SIPP does provide important information about relative differentials between subgroups of the population, e.g. between Black and White households, between married-couple and other households, and between high and low income households. The use of the feedback technique did not affect the cross-sectional estimates. The feedback approach provided results which were consistent with the expected differentials in net worth.

When we examined estimates of change based on cross-sectional estimates of mean or median net worth, we found few changes which were statistically significant for the feedback or control group. We also examined microlevel changes in net worth using only households with fully reported wealth data. We found some evidence that the feedback approach reduced the estimates of the change. In addition, the feedback approach provided a higher R^2 when a savings model was estimated. It is possible that the technique of providing previously reported data to respondents during the interview may lead respondents to give more careful consideration in their answers. However, the results also suggest that a one year time period between the point estimates may be too close to measure changes in net worth. Net worth is

fairly stable and household survey estimates suffer from sampling and nonsampling errors. For these reasons, a longer time period between point estimates may be necessary to measure significant changes in net worth.
