Decennial Statistical Studies Division

Subject: Assessment of the Addition of the Internet Mode to the American Community Survey Housing Unit Primary Selection Algorithm

Attached is the final Assessment of the Addition of the Internet Mode to the American Community Housing Unit Primary Selection Algorithm report. The assessment evaluates our current methodology for choosing among returns when a housing unit responds to the American Community Survey more than once. The method, the Primary Selection Algorithm, recently changed to handle cases received via the new Internet mode. The report also investigated the algorithm's handling of cases received via Telephone Questionnaire Assistance.

If you have any questions about this report, please contact Mark E. Asiala (301-763-3605) or Joseph C. Powers (301-763-3604).

## 1. Executive Summary

Spurred by the introduction of the Internet mode of data collection to the 2013 American Community Survey (ACS), statisticians at the U.S. Census Bureau conducted an evaluation of the Primary Selection Algorithm, the method used to choose a return when a housing unit responds more than once. The ACS Primary Selection Algorithm uses an unweighted ratio of item completeness, called the return quality index to decide between multiple returns. We saw no evidence of any flaws in the current Primary Selection Algorithm that would require immediate correction for the next round of annual ACS estimates for release in 2015.

Research Question 1: How often does the Primary Selection Algorithm's 20-percentage-point bonus for mail and Telephone Questionnaire Assistance returns result in the selection of a mail or Telephone Questionnaire Assistance return over an Internet, computer-assisted telephone interview, or computer-assisted personal interview return? (This question refers to the practice of giving a bonus to mail and Telephone Questionnaire Assistance return quality index values.)

- The bonus changed the results of the Primary Selection Algorithm for 3,855 pairs of returns in 2013. There was no clear trend across panels.
- Of the 3,855 pairs of returns, only about 4.0 percent ( 155 pairs) consisted of Telephone Questionnaire Assistance and either Internet, computer-assisted telephone interview, or computer-assisted personal interview. About 43.2 percent ( 1,665 pairs) consisted of a mail return and an Internet return, about 37.5 percent ( 1,445 pairs) were mail and computer-assisted telephone interview, and about 15.3 percent ( 590 pairs) were mail and computer-assisted personal interview.

Research Question 2: How does the return quality index compare between the various modes?

- We discovered the completeness score for vacant computer-assisted telephone interview and computer-assisted personal interview cases has been based on incorrect assumptions about the ACS questions that are eligible to be asked, leading to a correction for 2014 processing.
- For occupied units, Internet returns generally have completeness scores comparable to computer-assisted personal interviews, with 54.8 percent of the Internet returns having a completeness score of 90 percent or more, and 89.8 percent of them having a completeness score of 80 percent or more. The equivalent rates for computer-assisted personal interviews are 56.6 percent and 91.8 percent, while for computer-assisted telephone interviews or Telephone Questionnaire Assistance, they were 37.6 percent and 92.7 percent, and for mail they were 43.6 percent and 74.4 percent.

Research Question 3: What is the impact of treating Telephone Questionnaire Assistance returns similar to the computer-assisted telephone interview or computer-assisted personal interview returns in determining completeness?

- For the 2,370 cases in 2013 with a Telephone Questionnaire Assistance and nonTelephone Questionnaire Assistance return, the Primary Selection Algorithm chose the Telephone Questionnaire Assistance case 2,166 times (91.4 percent) under the existing rule. If the Primary Selection Algorithm treated Telephone Questionnaire Assistance as a computer-assisted telephone interview return (and resolved Telephone Questionnaire Assistance vs. computer-assisted telephone interview exactly like Internet vs. computerassisted telephone interview), it would choose the Telephone Questionnaire Assistance return only 1,787 times ( 75.4 percent).
- Stated differently, changing this part of the Primary Selection Algorithm to treat Telephone Questionnaire Assistance like computer-assisted telephone interview, rather than like mail, would result in 379 more non- Telephone Questionnaire Assistance returns being picked ( 16.0 percent), assuming only mail receives the 20 -point bonus.

Research Question 4: How does the distribution of item nonresponse compare between the modes?

- Similar to the discovery in Research Question 2 above, we discovered that the contributions to completeness score for certain items are not calculated correctly for all modes. In particular, the Telephone item for Telephone Questionnaire Assistance and computer-assisted telephone interview, the three questions related to grandchildren for all modes, and the three computer items do not have the correct universe definitions. Unlike the issue in Research Question 2, we did not detect this problem in time to correct 2014 Edit Input processing.
- There was no clear pattern for the Internet mode, with some variables having higher nonresponse for Internet compared to mail, and some lower.

Research Question 5: When two returns have similar completeness scores, how do they differ in the components of the completeness score?

- Even limited to pairs of returns where the Primary Selection Algorithm bonus was the deciding factor, there was no clear pattern.

## Conclusion

Although the error in calculating completeness score for vacant returns in some modes required fixing, and further errors still need correcting, the Census Bureau feels that the overall strategy of using the return completeness score as the basis for the Primary Selection Algorithm is sound. The merit of a bonus to completeness score for self-response returns in the Primary Selection Algorithm remains an area of ongoing research.

## 2. Introduction

With the 2013 data year, the American Community Survey (ACS) for the first time included an Internet response option. With the creation of this new mode of data collection came many changes to the existing processing systems. ACS data collection has always allowed for the possibility of multiple responses from its housing unit (HU) sample units during data collection operations. After data collection, but before the data are edited or weighted, multiple returns from an address are pared down so that each sample unit with more than one return has only one return passed into the edits and weighting. About 1.45 percent of the sample addresses have more than one return (Fish, 2014). The step for choosing which return among several is called the Primary Selection Algorithm (PSA), and is part of the edit input operation.

From the earliest days of the ACS, the PSA has favored interviews over noninterviews and records determined to be deletes, and favored noninterviews over deletes (Love, 1997). The ACS considers a vacant record to be an interview, because certain housing unit characteristics are collected from every HU, and other characteristics are collected specifically from vacant units. When choosing between two interviews, the PSA determines how to choose based on the combination of returns received. If both were mail interviews or if one is mail and the other is the respondent calling the Census Bureau (in an operation known as Telephone Questionnaire Assistance (TQA), the PSA selects the return received first in time. If one of the multiple returns was not a mail or TQA return, the PSA will use return completeness. In cases with three returns, the PSA selects the earlier of the mail or TQA returns, and compares the survivor to the third return on the basis of return completeness. Since the implementation of the Internet mode, it is no longer possible for most addresses to respond with two mail forms. Prior to the introduction of the Internet mode to the ACS, the PSA awarded a bonus to the score used to choose among returns to those returns that came via mail or by TQA. Historically, the bonus was given to these modes because of a preference for self-response (Love, 1997). Now that Internet-eligible addresses no longer receive two mail questionnaires, the only situation in which the PSA treats such an address as having two mail returns is when one return is via mail and the other is via TQA. The Internet response is new, and it was unclear what the data quality and pattern of item nonresponse would be. In particular, because of concern about Internet break-offs, the Internet mode did not receive the self-response bonus the mail forms receive in the PSA. Thus, for 2013, the PSA gives no preference to Internet returns over computer-assisted telephone interviewing (CATI) or computer-assisted personal interviewing (CAPI) returns, and mail returns receive a bonus over Internet, CATI, and CAPI returns.

Although the PSA used in the 2010 Decennial Census is too sensitive to discuss in open literature, there were some public evaluations of the PSA for the Census 2000 (Baumgardner, 2002 and 2003). Return completeness is a critical component of the ACS PSA, and Clark (2014) studied item nonresponse using data from the first six panels of 2013. Because ACS interviewing runs for three consecutive months, Fish (2014) examined the case of multiple returns, where one
return corresponds to an occupied interview and another return corresponds to a vacant interview. The ACS PSA was first articulated in Love (1997).

The purpose of this evaluation was to assess the current PSA methodology in light of the new data collection methodology. We also checked if the method of deciding between sample returns when respondents complete two or more ACS questionnaires now that the Internet mode of data collection has been implemented works as expected. Further, we checked if the current practices of favoring mail returns over other modes, and treating TQA returns as mail returns, are optimal.

Results from this report will help determine if the program should consider any changes to the PSA, and may lead to further research.

## 3. Overview of the American Community Survey Data Collection

This section contains an overview of the ACS and description of terms and concepts key to understanding this report. For further detail, consult the ACS Design and Methodology document (Census Bureau, 2014).

The ACS uses a series of monthly samples to produce annually updated estimates for the same small areas (census tracts and block groups) formerly surveyed via the decennial census longform sample. The monthly samples are also known as sample panels, or just panels, and a unit in a particular panel, for instance, June, 2013, will often be described as "from the 201306 panel." For 2013 data collection, a unit's panel does not depend on the time at which the unit responds to the ACS though by design they frequently coincide ${ }^{l}$. Data collection efforts for a unit last for approximately three months: Late in the month prior to the unit's panel month, we send the unit a prenotice letter to inform the household they have been selected for the ACS. The next mailing, which also goes out prior to the panel month, is the initial mail package and includes an instruction card for the Internet instrument ${ }^{2}$. Three days later, sample units receive a reminder postcard. If the unit has not responded, about two-and-a-half weeks after the initial mail package mailing, we send a replacement mail package containing a paper questionnaire and prepaid return envelope. Three days after the replacement mail package, sample units receive another reminder postcard. Finally, at the start of the month after the panel month, households that did not respond via mail or Internet, and for which the ACS has no phone number, receive an additional postcard telling them the ACS may contact them in person. For units that have not responded to the replacement mailing for which we have a telephone number, early in the month after their panel month, we attempt to contact them via the telephone phase, CATI. Just before the second month after a unit's panel month, we draw a sample of units to follow-up with a

[^0]personal visit from a field representative in the final phase, CAPI. Thus, every month of the year, three phases of ACS data collection are underway, and each housing unit in sample has a threemonth window to respond to the ACS. It is also possible for a unit to call us and complete the ACS via TQA.

The Internet, TQA, CATI, and CAPI instruments all have similar flow of questions. The first questions determine if the housing unit is vacant or occupied, and if occupied, then by how many residents. Second, basic demographic information on the residents is assembled in a roster. These data items are sometimes referred to as "100 percent items," as they are also items collected on the decennial census. After rostering, the third section of the instrument is a series of questions about the housing unit's characteristics; vacant units are asked a subset of these items. The fourth and final set of questions includes detailed person items for each person on the roster, which correspond to the person-level questions from the decennial census long-form survey.

## 4. Research Questions and Methodology

We evaluated the 2013 HU edit input (EI) outputs and analyzed certain operational variables the HU EI operation generates using files described below. These operational variables were: the completeness measure, QIND, which is made up of the HU-level indicator of HU item completeness (HSTRING) and the person-level indicator of item completeness (PSTRING). HSTRING and PSTRING are strings of indicator variables; each position in the string takes the value " 1 " if the item corresponding to that position was eligible to be asked and was answered, the value " 0 " if the item was eligible but not answered, or the value "." if it was not eligible.

HSTRING contains thirty housing unit items, while PSTRING holds fifty-two person-level items for each person in an occupied housing unit. The completeness measure QIND is calculated as the ratio of items answered over items eligible to be answered, and is therefore the ratio of the number of instances of " 1 " appearing in a housing unit's HSTRING and PSTRINGs (if any) to the number of instances of " 0 " or " 1 " in HSTRING and the PSTRINGs, multiplied by 100 (to make it a percentage). Full documentation of the correspondence of ACS questions to positions in PSTRING and HSTRING can be found in Appendices D and E of the HU edit input specification, respectively (Powers, 2014).

This research used unedited data from the January through December 2013 ACS sample panels collected in time to be part of the data tabulated for the 2013 ACS estimates. The research excluded data from the 2012 sample panels that happened to be collected in 2013, as well as any data from 2013 sample panels received after the cutoff date of March 20, 2014.

Because the research questions concerned our handling of the individual returns, and not the characteristics of the U.S. population, we used unweighted statistics in the analysis.

The research questions of interest were:

1. How often does the PSA's 20-point bonus for mail returns result in the selection of a mail return over an Internet, CATI, or CAPI return?
2. How does the questionnaire completeness score QIND compare between the various modes?
3. What is the impact of treating TQA (telephone questionnaire assistance) returns similar to the CATI/CAPI returns in determining completeness?
4. How does the distribution of item nonresponse compare between the modes?
5. When two returns have similar completeness scores, how do they differ in the components of the completeness score?

## 5. Results

## 1. Distribution of Quality Index Differences by Panel and Mode

Table 1.0, included below in the attachment of tables, shows the distribution of the differences in QIND, the return quality index, between mail or TQA returns and the QIND for Internet, CATI, or CAPI returns. The rows show the difference in QIND. The columns show the panel month. By construction, the mail or TQA return is the first term of the difference, so positive values mean the mail return's QIND was larger than the QIND in the other mode, while negative differences mean the non-mail, non-TQA mode return had the higher QIND. Note that there is no panel month for 201310 because of the Federal government shutdown of October $2013^{3}$. Comparing the distributions across panel, the interval $[0,10)$ shows an increase in the November and December panels, possibly a result of changes in follow-up because of the federal government shutdown. For instance, a larger than usual workload in the post-shutdown panels could have led to less aggressive follow-up than usual, slightly reducing the QIND of the follow-up mode.
Overall, Table 1.0 shows a longer tail in the negative differences, with 6,099 cases where the mail or TQA return had lower QIND than the other mode (out of 38,198 pairs of differences), and the bulk of the cases with the mail or TQA QIND as high or higher than the other mode.

In Table 1.0 the distribution of the differences also show a bimodal pattern, with the largest number of differences falling in the interval $[0,10)(5,028$ cases) and a comparable number in each of the intervals $[30,40)$ and $[40,50)(4,784$ and 4,823 cases respectively). The bimodal pattern in the distribution of differences between the mail or TQA return and a return in another mode comes from the mode of the second return (that is, the one that is not mail or TQA). Tables

[^1]1.1-1.6 break Table 1.0 to compare just mail and each of Internet, CATI, and CAPI (in Tables 1.1-1.3), and just TQA to each of the Internet, CATI, and CAPI modes (in Tables 1.4-1.6).

Considering the distribution of differences restricted only to cases of mail and Internet, shown in Table 1.1, there is a much smaller spike in $[0,10$ ), while the categories $[30,40)$ and $[40,50)$ have large peaks. Conversely, when the other mode is CATI or CAPI (respectively, Tables 1.2 and 1.3), the distribution peaks in $[-10,0)$ and $[0,10$ ), and drops off sharply thereafter. Additionally, the effect of the shutdown is limited to the CATI/CAPI distribution, as Table 1.1 reveals the mail vs. Internet distributions for November and December are similar to the earlier panels.

Comparing Table 1.1 to Table 1.0 shows that in the majority of the cases where we have two returns, those returns are from the Internet and mail. The 29,918 returns on Table 1.1 are more than 78 percent of all the cases with multiple returns (as seen on Table 1.0). Also on this table, the possible effect of the government shutdown is not as clear, as the distributions of QIND differences for the November and December panels are more similar to those of the other panels. However, we do see an increase in total to 2,944 for the 201309 panel and drops for 201311 and 201312 to 2,556 and 2,380 . The salience of the shutdown could explain why more respondents in the September panel responded in multiple modes than earlier panels. Likewise, the resumption of the ACS after the shutdown could explain why fewer respondents in the November and December panels responded multiple times.

In Table 1.2, the mail and CATI return combination makes up about 11 percent of all cases with two returns. Here the distribution is markedly different from prior tables, as the distribution of differences centers near zero. Further, in general, the mail returns have lower QIND, as the intervals below zero have higher frequencies than the intervals above zero. Table 1.2 also has the November and December panels as the most frequent panels for this combination of modes, consistent with changes to the ACS follow-up after the government shutdown. However, the 201302 panel is the third-most frequent panel for this combination, and is similar to the 201312, so the shutdown may not be the only factor at work. The mail and CAPI return combination appears in Table 1.3 (about 5.5 percent of Table 1.0), and this distribution more closely resembles the mail and CATI combination than mail and Internet.

Analyzing TQA compared to Internet, CATI, and CAPI modes shows that, overall, these combinations of two returns are infrequent. Table 1.4, which shows the returns with TQA and Internet responses, is about 4.6 percent of all cases with two responses. Table 1.5 contains just the returns with a TQA and a CATI response, while Table 1.6 contains just the returns with a TQA and a CAPI response. Tables 1.5 and 1.6 are only about 0.21 percent and 0.28 percent of cases with two responses. While it is reassuring that so few cases in the CATI and CAPI phases also respond by TQA, the sample sizes for Tables 1.5 and 1.6 ( 81 and 108) make it difficult to draw any conclusions. However, Table 1.4 does show an interesting bimodal pattern, with more than 10 percent of its returns in the interval $[0,10)$, and a peak around $[50,60)$. As most of the
differences on Table 1.4 are positive, this suggests that most of the respondents were willing to respond to most ACS questions, but may have been unable to complete them via the Internet, perhaps because they lost their passwords or were unaware they needed a password to return to the Internet instrument, thus becoming insufficient partial interviews. The cases near zero could represent people who filled out an Internet response late enough in time that the mail questionnaire was already on its way, and then called in to TQA after they received it. Also of note, in Table 1.4 we do not see any differences in the distributions of QIND differences between the November and December panels and the earlier months.

Under the existing PSA, mail and TQA cases receive a 20-point bonus to their QIND scores compared to the other modes. The intervals $[-20,-10)$ and $[-10,0)$ from Table 1.0 combine in Table 2.0 to show this bonus is the deciding factor in which return the PSA selects 3,855 times.

Tables 2.1-2.6 break Table 2.0 out by mode just as Tables 1.1-1.6 break out Table 1.0. That is, Tables 2.1, 2.2, and 2.3 are the components of Table 2.0 corresponding to units that respond by mail and Internet, mail and CATI, and mail and CAPI respectively, while Tables 2.4-2.6 correspond to units that respond by TQA and Internet, CATI, and CAPI. It is rare for the TQA cases to have a quality index such that giving them the 20-point bonus would change the result of the PSA. Cases with TQA and another mode (Tables 2.4-2.6) contribute only 155 of the 3,855 cases with two returns and a QIND difference in the interval [-20, 0) (Table 2.0) (4 percent, and just 0.4 percent of the cases with two returns). In fact, fully 43.2 percent of the cases in which the PSA bonus changes the result come from the mail and Internet combination, while the mail and CATI combination contributes 37.5 percent and the mail and CAPI combination contributes 15.3 percent. It may not make sense to award the bonus to cases in the mail versus Internet combination, because the response pattern is so different from the mail versus CATI/CAPI distributions.

## 2. Distribution of Quality Index by Mode

Tables 3.0-3.2 show the distribution of QIND divided into 10-percentage-point intervals for all interviews, including units with one return and units with three returns, not just two returns as in Section 5.1. The distribution for QIND for the mail returns does not include the twenty-point bonus, so that all modes are shown with the range of 0 to 100 , rather than 20 to 120 for mail and 0 to 100 for all the other modes. However, in cases with multiple returns, only the return the production PSA selected is included. This return is referred to as the selected return. As the ACS considers a vacant housing unit an interview, but the set of questions asked of vacant units differs from those asked of occupied units, the occupied and vacant units are analyzed separately. The ACS also has two categories of vacancy, temporary and regular, but this analysis collapses them together. Table 3.1 examines the distribution of QIND by mode of the selected return when the selected return is occupied; Table 3.2 considers the same distribution when the selected
return is vacant ${ }^{4}$. Note also that the tables do not include the QIND values for the return or returns the PSA rejected.

Turning to the distribution of QIND by the mode of the selected return in Table 3.0, the Internet returns generally have the best quality, with more than half of Internet returns having QIND in [90, 100], and more than 88 percent in [80, 100]. For the mail mode, 43 percent had QIND in [90, 100] and only 74 percent had QIND in [80, 100]. For CAPI, only 39 percent had QIND in [90, 100], and 63 percent had QIND in [80, 100].

Because of a mathematical artifact of the construction of QIND, the distributions of vacant and occupied QIND must differ ${ }^{5}$ regardless of mode. However, as seen in Tables 3.1 and 3.2, the distribution of QIND is also notably bimodal for CAPI (and to a lesser extent for mail, TQA, and CATI), and the bimodality owes to the difference in QIND distributions for occupied versus vacant units by mode. In Table 3.2, only five TQA, CATI, and CAPI vacant cases had QIND as high as 60 . This outcome is under further investigation, as it may be because the rules for calculating QIND do not properly account for the question skip patterns in the CATI and CAPI instruments. The distribution for vacant mail returns is also different from the distribution of vacant Internet returns, as 40 percent of vacant mail cases have QIND in [80, 100], while only 14 vacant Internet cases out of 10,778 were in this interval. (QIND can be non-zero for vacant units because QIND includes certain housing unit items, such as the number of bedrooms, for which every HU is eligible.) For occupied units only, nearly 90 percent of the Internet returns had QIND in [80, 100], while only 74 percent of mail returns fell in the same interval.

## 3. Experimental Primary Selection Algorithm

Under the existing PSA, TQA cases are treated as if they were mail cases because a TQA return occurs when the respondent replies without further prompting (as in CATI or CAPI). In the 2013 data, there were 2,370 cases where the PSA had to choose between a TQA case and a return in another mode (including mail). Under the existing PSA, it chose the TQA 2,166 times (91.4 percent), as shown in Table 4.0. Under an alternative treatment, where TQA is treated as a CATI return (and TQA vs. CATI choices are resolved the same as Internet vs. CATI/CAPI), the PSA would choose the TQA return only 1,787 times ( 75.4 percent). The 379 cases that change

[^2]between the two treatments of TQA are 16 percent of the cases examined. Thus, altering the PSA to treat TQA as CATI (their instruments are very similar) would not drastically change the composition of returns the PSA selects. Additionally, these cases do not sum to the entries on Tables 2.4-2.6 because the results of this experiment are not directly comparable to the results discussed above, as this experiment included two-return combinations of mail and TQA. The PSA does not use QIND in this two-return combination, so these cases were excluded from the analysis of Section 3.1 above.

## 4. Item Response Rates by Mode

Table 5.0 presents the item response rates by all five response modes for the thirty housing unit items used in calculating QIND. The denominator of the rate is the number of times the edit input QIND algorithm indicated that the return was eligible to answer the item; the numerator of the rate is the number of times the edit input QIND algorithm found the unit to have an answer to the item. Only housing units with at least two responses were included, but units with exactly two mail responses were excluded. Further, these item response calculations include both the accepted and rejected response. Table 6.0 presents the item response rates for the fifty-two person items used in calculating QIND occupied units. In occupied housing units with more than one person, each person contributes to Table 6.0 those items for which he or she is eligible. Response rates were calculated without weighting the data.

This analysis uses QIND calculations consistent with those in production edit input, although we discovered that the universe definition for some items used to calculate QIND was incorrect. TQA and CATI cases are not asked the telephone service item, since it would be redundant. The existing edit input procedure expected this item to have been automatically filled with a 'yes' answer in these modes, but this is only done after edit input. In fact, these modes are not eligible to be asked this question, so their cells on Tables 5.0-5.2 incorrectly show $0 \%$ response. Likewise, the Computer Use, Internet Access, and Internet Subscription items on these tables have incorrect definitions, leading to an underestimate of the true response rates. Finally, on Tables 6.0-6.2, the Grandchildren Living at Home, Responsible for Grandchildren, and Months Responsible for Grandchildren items have counts of eligible cases that are all too high, underestimating the true response rates. These flaws will be corrected with edit input for the 2015 data in March 2016.

Analyzing the item response rates by mode for the housing unit items in Table 5.0 shows a mixed pattern for the Internet mode. Item response rates such as for Property Value show response rates close to those of mail, but some item response rates were closer to the CATI/CAPI rates, such as the Monthly Electricity Cost. A few items diverged from the rate for mail, such as Monthly Condominium Fee. The most obvious pattern in Table 5.0 is that the Internet mode shows generally the lowest item response rates for many items of all the modes, such as Number of Bedrooms, Number of Rooms, and Receipt of Food Stamps. This might occur if respondents break off from the instrument after completing the household roster, as the housing unit items
appear after basic demographic questions such as Sex and Age but before detailed person-level items such as English Ability or Educational Attainment.

Tables 5.1 and 5.2 show the item response by mode for housing unit items limited to pairs of returns for which the difference in the quality index between the returns falls in [-20, 0), with 5.1 containing only the returns the PSA selected, and 5.2 the returns the PSA rejected. Thus, the mail returns on Table 5.1 were selected over a competing response with a lower QIND because of the bonus in the PSA. Because their selections were often driven by time of arrival rather than item completeness, TQA returns are excluded from these tables.

No clear pattern in the item responses emerges, though Table 5.1 shows that the mail returns have much higher overall item response rates than the Internet returns in the same table. In Table 5.2 we see the reverse; the response rates are higher for the Internet than the mail.

The item nonresponse patterns in Table 6.0 are similar to those seen in Table 5.0, as the basic demographic item response rates (Sex, Age, Marital Status, Hispanic Origin, and Race) are high for Internet returns (with the exception of Marital Status), and decrease thereafter on the detailed person items. The Internet response rates for Citizenship and Ancestry decreased from those of the most comparable mode (mail), and for items such as English Ability, were much smaller than the best mode. (For English Ability, the item response rate for mail was 77.9 percent, while for the Internet, the rate was 42.7 percent.)

Tables 6.1 and 6.2 are analogous to Tables 5.1 and 5.2, in that they analyze the item response rates for person items by mode, restricted to pairs of returns where the difference in the quality index is in the range $[-20,0$ ). Table 6.1 contains the returns the PSA selected, while Table 6.2 holds those it rejected. As with Tables 5.1 and 5.2, TQA returns are excluded from these tables. The stark difference between the Internet returns on Table 6.1 and the mail returns shows that some Internet respondents break off the interview before completing the detailed person items, which come after the basic information gathered in creating the roster at the housing unit, and after collecting the housing unit items.

## 6. Conclusions

Importantly, we found no evidence of any flaws in the current PSA that would require immediate correction for the next round of annual ACS estimates to be released in 2015.

From our review of the distribution of return completeness, we saw no reason to give mail but not Internet responses a 20-point QIND bonus in the PSA selection. It remains a topic for future research whether the self-response returns in general merit a 20-point bonus in QIND in the PSA. We add that there may be reason to be less concerned about the effect of having an interviewer collect the ACS data from respondents now than in the early days of the survey. ACS field interviewers have more familiarity with the survey than would temporary employees hired to conduct a long-form survey during a decennial census.

The addition of the Internet mode has changed the population of the ACS respondents who respond to the ACS in more than one mode, as Table 1.1 shows a different pattern of responses than Tables 1.2 and 1.3. Patterns in the Internet responses suggest that respondents who respond by the Internet and another mode may have lost their passwords to re-enter the Internet instrument, instead of being reluctant to respond to the ACS. Because the population of cases the PSA must resolve has changed, it may be worth revising under what circumstances a mail return should receive a bonus to its return quality index in the PSA. For instance, the PSA could apply the bonus only to mail returns when the other mode is CATI or CAPI, not Internet, or the PSA could do away with a bonus for mail returns entirely.

Table 4.0 shows that changing the PSA to treat TQA as a CATI return would not change the PSA results dramatically. In the case of TQA vs. another mode, in only 379 cases would we expect the PSA results to change, and in many of those cases (the mail vs. TQA cases) the results would go from being determined by the return received first to being the return with higher data quality, even allowing for the mail retaining a bonus. Therefore, it may be worth changing the PSA to treat TQA more like the instrument that collects it (CATI), rather than grouping it with mail returns because it is a self-response.

Although this study did not examine the case of two mail returns (which only happens in the Puerto Rico Community Survey) or the case of a mail return and a TQA return (which is currently handled in the PSA just as if both returns were mail returns), future research may address whether the ACS preference for the earlier return is justified given the responses we have seen.

[^0]:    ${ }^{1}$ One exception is for those HU determined to be unreachable by mail, or unmailable. They are contacted by personal visit two months after their panel month. Since they cannot respond by more than one mode, they are not relevant to this study.
    ${ }^{2}$ In some cases, this mailing arrives and the unit responds via the Internet prior to the panel month. Such interviews are treated as happening in the panel month.

[^1]:    ${ }^{3}$ Because of the 2013 government shutdown (October 1- October 17), the ACS did not have a second mailing, a telephone followup, or a person followup operation for the October 2013 housing unit panel. Only respondents from the first mailing (Internet in the United States, paper questionnaire in Puerto Rico) contributed to the overall response for this panel. Additionally, the CATI follow-up for the September housing unit panel extended through November, with CAPI in December, and the CAPI for the August housing unit panel extended through November.

[^2]:    ${ }^{4}$ Unit status (whether occupied or vacant) is not set for returns not selected by the PSA, so this analysis does not distinguish between cases where all returns have the same status versus cases where they differ (some occupied, some vacant). See Fish (2014) for a discussion where status differs in multiple responses.
    ${ }^{5}$ Vacant units are eligible for only a few housing unit items to calculate their QIND (ten items all housing units are eligible for, plus two asked only of vacant units [see Table E-1 of [Powers, 2014] for the list of items). As a result, their QIND values can take on only thirteen values between zero and one, corresponding to zero twelfths, one twelfth ... twelve twelfths. Occupied units contribute person-level items for each person, as well as more housing unit items than vacant housing units, so the QINDs of occupied unit vary more than QIND for the vacant units. Since both the number of people in an occupied unit and the person-items each person is eligible to be asked are random variables, the QIND distribution for occupied units is finer, i.e. has many more possible values in $(0,1)$ than for vacant units. More formally, given that a return is vacant, the denominator of its QIND must be twelve with certainty, while given that a return is occupied, the denominator of its QIND is still a random variable.
